Abstract

Many pesticides used in agriculture have a negative effect on organisms. The group of hazardous pesticides includes the cholinesterase inhibitor bendiocarbamate. According to literature, bendiocarbamate has relatively low toxicity in mammals and vertebrates in general, since it does accumulate in their tissues and the cholinesterase activity returns to norm within 24 h after acute exposure. The present study focused on the influence of bendiocarbamate on rabbit thymus after its administration at a dose of 5 mg/kg body weight (BW) for the period of 3 months. The thymus was observed for acetylcholinesterase (AChE) and butyrylcholinesterase (BuChE)-positive nerve fibers visualized by histochemical methods. Microscopic findings of BuChE - positive nerve fibers show the same density and the topography by the experimental and the control animals. On the other hand, AChE - positive nerve fibers in experimental animals after administration of bendiocarbamate is only poorly identified, suggesting that bendiocarbamate inhibits AChE but not BuChE.

Introduction

Recently, a large amount of chemicals are produced, which come into close contact with the human body. Agrochemicals are an certain part of modern agro-technical procedures despite the fact that a great number of them are on the list of risk substances. Many agrochemicals have toxic and genotoxic effects and, subsequently, after cumulative somatic mutations, also carcinogenic effects. Uncontrolled and thoughtless use of various pesticides resulted in health problems involving nervous, endocrine, reproductive and immune systems of animals and humans. Although some pesticides have been restricted or banned because they pose risks of cancer, birth defects, or neurological damage, little attention has so far been given to what may be their greatest health risk: impairment of the immune system. Hundreds of experimental studies on human cell cultures and animal models provide strong evidence that many pesticides are immunotoxic and may affect immune status and function.

A range of pesticides belongs to the group of cholinesterase inhibitors involved in morphogenesis. Cholinesterase inhibitors are a group of chemical substances precluding hydrolysis of acetylcholine and thus causing accumulation of acetylcholine in reactive sites of live organisms. Inhibition of brain acetylcholinesterase has been the major therapeutic target for Alzheimer disease and other patients with dementia. One of the cholinesterase inhibitors, bendiocarbamate, is used to control insect populations. Bendiocarbamate (2,3-isopropylidenedioxophenyl methylcarbamate) is a pesticide acting upon invertebrates by irreversibly blocking the activity of the enzyme cholinesterase, which is critical in allowing muscle relaxation by removing the neuromuscular mediator acetylcholine. It has relatively low toxicity in mammals and vertebrates in general, since it does accumulate in their tissues and the cholinesterase activity returns to norm within 24 h after acute exposure. The clinical picture of bendiocarbamate intoxication includes diarrhoea, vomiting, dehydration, loss of weight, alopecia, hypersalivation and muscle tremor. Many studies proved that bendiocarbamate increases incidence of lymphoreticular tumours, such as lymphomas, reticulosarcomas, lymphoid and myeloid leukaemia. Presently, the acute oral toxic dose for adult experimental animals is as follows: rat 34-156 mg/kg body weight (BW), rabbit 35-40 mg/kg BW and guinea pig 35 mg/kg BB. The thymus is a central lymphoid organ with an important endocrine function. It is a place where the T cells precursors proliferate and mature, these are responsible for the cell-mediated immunity. The main role of thymus-derived lymphocytes is the protection against the tumourous cells, intracellular parasites and viruses; through cytokine secretion they activate other cells of the immune system. During the prenatal and postnatal period, patological involution of the thymus may occur in response to any form of acute stress. It may be associated with environmental toxicants, trauma, severe infection, chemotherapy, smoking, hormonal therapy or malnutrition. Not all factors influencing the size and function of thymus are known.

Animal cholinesterases are widespread enzymes present in cholinergic and non-cholinergic tissues as well as in their plasma and other body fluids. They are divided into two classes according to differing in their substrate specificity, behavior in excess substrate and susceptibility to inhibitors: acetylcholinesterase or true cholinesterase (AChE) and butyrylcholinesterase (BuChE). BChE is also known as non-specific cholinesterase or simply cholinesterase. The aim of this study was to compare the effects of bendiocarbamate on histochemical localization of acetylcholine- and butyrylcholine-positive nerves in rabbit’s thymines.

Materials and Methods

The study was carried out on 50 European rabbits (Oryctolagus cuniculus), hybrid Hyla, of both sexes. The rabbits were 54 days-old with mean BW of 1250 g. The experimental animals were kept under standard conditions in animal quarters at 15-18°C and natural light regimen. They were fed granulated mixed feed and were supplied drinking water ad libitum.

The rabbits were placed into large litter less cages, 6 animals in each. The experimental animals were administered bendiocarbamate (96% Bendiokarb tech., Bayer, Leverkusen,
Germany) in the form of capsules per os at a dose of 5 mg/kg BW daily for 13 days. Since the animals showed a strong response to the daily administered dose (diarrhoea, dehydration and alopecia in some animals), after 13 days the exposure was decreased by administering the same dose in 48 h intervals. During the experiment, control animals were fed standard granulated mixed feed intended for rabbits. On days 3, 10, 20, 30, 60 and 90 of the experiment, groups of experimental animals consisting of 6 rabbits were euthanized by ether together with control group (8 rabbits) of animals. The experiment was conducted in compliance with the rules set by the Ethical commission of University of Veterinary Medicine in Kosice, Slovakia and conditions for experiments on animals. Samples taken from the thymus were processed for demonstration of AChE-positive and BuChE-positive nerve fibers. During two hours the samples were fixed in 4% formaldehyde at 4°C. Sections were prepared on freezing microtome thick 20 µm and incubated in the incubation solution during the period of 2-4 h at 37°C. The incubation medium (according to method of Karnovsky and Roots \cite{18} and of El Badawi and Schenk \cite{19}) contained acetylthiocholine iodide. The exact composition of incubation solution can be found in Table 1, the final pH of solution was 5.6 to 6.0.

The exact composition of incubation solution was acetylthiocholine iodide needed for the visualization of specific AChE, tetraisopropylpyrophosphoramid (iso-OMPA) for inhibition of non-specific AChE was used. In this method acetylcholinesterase present in the cholinergic nerves releases thiococholine from acetylthiocholine which reduces potassium ferricyanide to potassium ferrocyanide, capable of producing insoluble copper ferrocyanide with copper ions (Hatchett’s brown).

The method for visualization of butyrylcholinesterase is the same, but the incubation medium contained butyrylthiocholine iodide as an inhibitor of specific AChE instead of acetylthiocholine iodide. The exact composition of incubation solution can be found in Table 1, the final pH of solution was 5.6 to 6.0.

Results

Nerve fibers of thymus

Rabbit thymus of control animals contained AChE- and BuChE-positive nerve fibers in two forms: i) nerve fibers joining to vessels. They formed networks around branches of vessels running in septa and, as a common bundle, headed to organ parenchyma. They entered the cortex layer of the thymus from subcapsular nerve network. The part of the cortex housing numerous lymphocytes was very poor in nerve fibers, while abundant nerve clusters could be observed at the level of corticomedullary junction, i.e. the part which was a primary starting point of cells and early precursors; ii) nerve fibers independent on vessels. They were most abundant at the corticomedullary junction and a little less frequent in the medulla.

Nerve fibers after administration of bendiocarbamate

Microscopic findings related to AChE-positive nerve fibers show the same density and the topography by the experimental and the control animals. On the other hand, AChE-positive nerve fibers in experimental animals after administration of bendiocarbamate is poorly identified, suggesting that bendiocarbamate inhibit AChE but not BuChE. Microscopical findings related to AChE-positive innervations of the thymus of rabbits which were administered bendiocarbamate, the inhibitor of AChE, were rather indistinctive (Figures 1 and 2). One could not identify nerve structures with certainty and AChE-positivity was exhibited only by non-neural cellular elements in all experimental materials examined (Figure 3). In the control animals the AChE-positive nerve fibers were observed in the organ capsule in cortex layer originating from the interlobular septum. Fine nerve fibers terminated in the cortex and frequently came to close contact with lymphocytes while in the deep cortex layer and medulla they were located close to epithelial cells.

The distributions of BuChE-positive nerve fibers after visualization were the same in experimental and control animals. Nerve fibers entered the thymus as a common bundle with

Discussion

The thymus played a key role in the evolution of animals during development of an adaptive immune system; it is therefore an important element, distinguishing higher vertebrates from other animals.21,22 Our observations of AChE and BuChE-positive nerve fibers in rabbit's thymuses proved their presence in interlobular septa, capsule, cortex, cortico-medullary junction and in the medulla. Our results are in agreement with the observations of authors who investigated autonomic innervations of thymuses in rats and mice.23,24 Functional changes after administration of cholinesterase inhibitors are characteristic of disorders of metabolic processes responsible for regulation of acid-base balance. Accumulation of acetylcholine results in depolarization of biologic membranes and hypokalaemia.25 It is well known that surface membranes of various subpopulations of lymphoid cells harbor a number of specific receptors of both conventional neurotransmitters and some peptides. According to Mignini et al.,26 released neurotransmitters may affect functions of T and B lymphocytes as well as the process of entrapping antigens by cells. Our observations of BuChE-positive thyme innervations that bendiocarbamate blocks specific cholinesterases but will not accumulate in the body of mammals, as after 24 h it is released from mammal tissues either by urine or by lungs or faeces, are in agreement with the results of Ratner et al.25

Long-term administration of bendiocarbamate caused a decrease in relative proportion of medulla at the expense of cortex which contained hyperplastic reticular cells. Our results allowed us to state that BuChE-positive innervations of thymus did not differ significantly between experimental and control animals, i.e. bendiocarbamate administered at a dose of 5 mg·kg⁻¹ BW failed to inhibit visualization of BuChE-positive nerve structures. On the other hand, AChE-positive nerve profiles were not visualized in experimental animals after administration of this substance. Bendiocarbamate can affect not only the thymic innervations, but also the dividing of lymphocytes. Holecková et al.27 investigated induction of the unstable chromosomal aberrations, sister chromatid exchange and stable chromosomal aberration after bendiocarbamate administration in cultured peripheral bovine lymphocytes. They found increase of chromatin breaks frequency. Varga et al.28 found significant positive correlation in thymic size and number of lymphocytes in peripheral blood in newborns.

It has been assumed that suppression of the immune system by some pesticides forms the basis for increased number of allergies, hyper-sensitivity of organisms and susceptibility to tumour growth.27,31 One of possible mechanisms of these observations is the oxidative stress: the action of xenobiotics is frequently associated with increased level of reactive forms of oxygen.32-34
